LIST OF SYMBOLS

- ω - Angular frequency of forced motion
- q - Dynamic pressure ($= \frac{1}{2}\rho V^2$)
- α - Pitching angle of wing, positive in direction of stall
- h - Vertical translation of wing at 37% chord, positive downward
- β - Angle between front and rear actuator wheels or as defined in Reference 13, angle between pitching and translatory motion
- b - Semi-chord length
- V - Airstream velocity
- K - Reduced frequency parameter ($= \frac{\omega b}{V}$)
- θ - Angle by which pitching motion leads translational motion
- L - Lift force on airfoil
- M - Moment on airfoil
- ϕ - Phase angle between motion and reaction for sinusoidal reactions or lag angle as defined in Reference 13
- C - Coefficient
- T_r - Characteristic time, defined in Section V
- K_r - Reduced frequency involving characteristic time (T_r)
- ΔC_M - Variation of C_M from static curve ($= C_{M_{\text{actual}}} - C_{M_{\text{Steady-State}}}$)
- λ - Dynamic slope of moment versus angle of attack curve.
- F - Theodorsen's Function as defined in Reference 15 ($= F(k)$)
- G - Theodorsen's Function as defined in Reference 15 ($= G(k)$)
- $C(k)$ - Theodorsen's Function as defined in Reference 15 ($= F(k) + iG(k)$)
- a - Ratio of distance of elastic axis aft of mid-chord point to semi-chord length

I - SUMMARY

The problem of stall flutter is approached in two ways. First, using the N.A.C.A. M.I.T. airfoil oscillator, the aerodynamic reactions on wings oscillating harmonically in pitch and translation in the stall range have been measured, evaluated and correlated where possible with available published data, with the purpose of providing empirical information where no aerodynamic theory exists. The major effects of Reynold's Number, airfoil shape, and reduced frequency on the aerodynamic reactions have been reaffirmed. No instances of negative damping were observed in pure translatory motion and the ranges of negative damping occurring in pure pitch had the same general trends noted by other experimenters. Data on the time-average values in the stall range of both lift and moment are presented for the first time.

Second, the results of numerous experimental observations of stall flutter have been reviewed and the various known attempts at its prediction have been examined, compared and extended. The sharp drop in critical speed and change to a predominantly torsional oscillation usually associated with the transition from classical to stall flutter is apparently primarily but not entirely caused by the marked changes in moment due to pitch. Fairly good stall flutter predictions have been reported only when adequate empirical data for this aerodynamic reaction happened to be available for the desired airfoil shape, Reynold's Number range and reduced frequency range. A semi-empirical method of predicting the variations of moment in pitch with airfoil shape, reduced frequency, initial angle of attack, and amplitude of oscillation has been presented.

II - INTRODUCTION

Stall flutter differs from classical flutter in that the flow over the airfoil is stalled during all or part of the cycle of oscillation. Although stall flutter has been observed in aircraft propellers for some time, new interest in the phenomenon has been generated by the advent of the aircraft gas turbine where turbine blade stall flutter is a serious problem. Even though it is known that the critical speed drops sharply from the value predicted by classical theory as portions of the flow begin to stall, no adequate prediction techniques have yet been proposed primarily because not enough is known about the behavior of the aerodynamic reactions in the oscillating partially stalled flow.

Work on stall flutter was begun in this laboratory in the summer of 1947 when the evaluation of the low angle of attack aerodynamic derivative data was completed (Reference 1). The M.I.T. N.A.C.A. airfoil oscillator was modified to operate in the stall range as described in the report on Phase 6, Reference (3) and a large mass of aerodynamic derivative data was accumulated which within its somewhat limited range gives a far more complete picture than has been heretofore available.

In this report (Phase 7) an attempt has been made to evaluate these data with comparison, where possible, with other available data. The information thus obtained was used in critically examining proposed stall flutter prediction techniques and actual stall flutter tests.

III - M.I.T. EXPERIMENTAL PROGRAM

The apparatus used in this research has been described in considerable detail in the previous reports of this series. (References 1 through 3). Reference 3 describes the modifications required to make the apparatus useful for studies at high angles of attack. A review of the various elements of the mechanism both mechanical and electrical, and a complete outline of calibration, testing and analysis procedures is contained in the following pages of this section.

3.1 Description of Apparatus

3.1(a) Actuator and Linkage. The mechanical features of the oscillator are shown diagrammatically in Figures 2a and 2b, which also briefly outline the functions of the various parts. The numbers in parentheses in the description below correspond to numbers of Figures 2a and 2b.

Power is supplied to the line shaft (1) by a 15 horsepower electric motor with a Ward-Leonard speed control. V-belts drive sheaves (2), which are geared to drive the crank wheels (3). These crankwheels all have variable amplitude cranks and connecting rods which drive the vertical crossheads (4) at oscillator frequency. The phase (β) between the front and rear pairs of crankwheels may be varied in increments of 3.75° with the use of the angular scale (15). The position indicator (6) gives the position of the rear vertical members and the position of the other members may be found if the phase angle (β) between the front and rear crankwheel pairs is known. Equations relating the motion of the cranks to other motions of the linkage are given on page 18 of Reference (1).

From the vertical crossheads the motion is carried to the cam (16) by steel bands (7). These bands are attached to the vertical crossheads by turnbuckles and to the cam by forks operating in ball bearings. A similar set of bands connects the cam to the springs (9) in the overhead structure, and the required initial band tension is attained by use of electric motors and gear trains (10). The motion of the cam is transmitted to the wing and accelerometers (17) through a four bar linkage. The vertical bar (18) at the cam center is free to move vertically so that the cam may translate vertically, pitch, or move in any combination of the two motions.

The three airfoils used in these tests were constructed of sycamore wood and .007" magnesium alloy sheet. The uncovered frame is shown in Figure 3. Airfoil section and ordinates are given in Figure 4.

3.1(b) Instrumentation. The instrumentation used in these tests is that of

Figure 5. The amplifying equipment, the bridge balances, and the recording oscillograph are products of the Consolidated Engineering Corporation.

1) The strain gages which measure lift, moment, drag, position and translational and pitching accelerations are supplied with 1000 cycle carrier voltage by an oscillator manufactured by the Consolidated Engineering Corporation. Four strain gage pairs are used to measure lift, two for drag, two for moment, and two each for pitching and translational acceleration.

2) The equalizer panel consists of 15 ohm potentiometers in series with each strain gage (200 ohms) so that the sensitivity of each strain gage may be varied individually, thus the strain gage outputs may be made equal under a given load.

3) The offset circuit utilizes resistances to unbalance the bridges by a known amount. Its purpose is to balance out the portion of the strain gage signal due to static lift, drag, or moment, at high angles of attack. Thus the oscillating portions may be rendered on the sensitive paper of the oscillograph at a reasonable amplitude, keeping the amplifier output within the linear range.

4) The bridge balance units consist of both a phase and resistance balance and are used to adjust the strain gage output to zero under any tare loading.

5) The position indicator serves to indicate reference points in the wing's cycle of motion.

6) The attenuator boxes are used only in the lift and moment inertia circuits for balancing the inertia signal from the accelerometers against that of the wing. A better understanding of their use and operation may be gained by reading the section on calibrations.

7) The amplifiers, as might be supposed, amplify and rectify the modulated 1000 cycle signals from the strain gages, for use in the oscillograph. The injected carrier shown feeding into the amplifiers in Figure 6 is used to provide a reference signal amplitude level so that the amplifier output shows the positive or negative sense of the signal.

8) The add circuit box serves the purpose of subtracting the inertia signal (from accelerometers) from the total (aerodynamic+inertia) signal in lift and/or moment. The box is equipped with a switch so that the operator can control whether the signals shall pass through the add box and appear separately on the oscillograph record, or whether the subtraction described above shall take place and only the aerodynamic portion of the signal be recorded on the sensitive paper.

9) The recording oscillograph utilizes high natural frequency galvanometers which deflect a beam of light on to sensitive paper for recording purposes. There are

Figure 5
Arrangement of Instrumentation.

MASSACHUSETTS INSTITUTE OF TECHNOLOGY
Department of Aeronautical Engineering

PAGE 12

CONTRACT NO. NAW-5693

14 channels available for use, 8 of which were used in these tests. The quantities measured together with their trace numbers are listed below:

1 - Lift	9 - Lift Inertia
3 - Drag	10 - Moment Inertia
5 - Position	11 - Lift Inertia
7 - Moment	12 - Moment Inertia

It will be noted that lift inertia and moment inertia are each given two oscillograph channels. The reason behind this apparent duplication is that one lift inertia and one moment inertia trace will not appear on the record after subtraction from the appropriate total aerodynamic reaction signals.

3.2 Testing Procedure and Analysis of Data

3.2(a) Linkage Setting and Adjustment. Immediately after assembly of the oscillator mechanism in the wind tunnel, careful adjustments of the linkage were made. These adjustments consisted of the following:

- 1) Adjustment of amplitude of each crank to prevent any relative motion between the left and right wing supports.
- 2) Adjustment of turnbuckles to level all elements in the zero amplitude position.
- 3) Check and adjustment of the clearances between the wing and end plates.

After the linkage was adjusted, it was set to give a pure pitching motion. This was accomplished by setting the amplitudes of the cranks equal, and with 180° phase angle between the front and rear cranks. Phase angles between front and rear cranks were obtained by pinning the rear cranks in position, unmeshing the driving gears and setting the phase angle with the aid of the scale adjacent to the front crankwheel, then remeshing the driving gears. The relation between this phase angle (β) and the angle between pitching and translational motion (θ) is given on page 18 of Reference (1), where also the equations for linear and angular amplitudes are given.

After the linkage was adjusted to give the desired motion, it was necessary to be able to set accurately the initial angle. A protractor incorporating a very sensitive level was used to measure the angle of the wing support strain gage beams with the horizontal. The angular measurements made with this device were quite accurate, being within ± 0.1 degrees of the desired value. In order to be certain that all four wing support points were in a plane, a leveling plate was used. After the initial angle was

MASSACHUSETTS INSTITUTE OF TECHNOLOGY
Department of Aeronautical Engineering

CONTRACT NO. NAW-5693

PAGE 13

set on the left side, the right rear element was lowered and the leveling plate was placed over the remaining three points. An adjusting screw was utilized to bring the rear element up into contact with the plate, the contact being indicated by a deflection of the needle on the dial of the amplifier attached to the moment bridge. This method permitted very accurate setting of the four supporting points so that their deviation from a plane was not greater than about .002 inches.

When the initial angle was set, the strain gage beams were loosened and removed, and the wing was placed between the end plates; then the strain gage beams were inserted in their slots and tightened, the removable fairing plates replaced, and the mechanical apparatus was ready for tests.

3.2(b) Calibration. Before any tests were actually run it was necessary to calibrate the equipment. The accelerometer circuits were provided with attenuators in the form of voltage dividers so that the accelerometer output could be varied from the full output to zero in .01% steps. Since the accelerometers were to be used to cancel the inertia signals of the wing, a device putting out the same inertia signal as the wing was indicated. The desired inertia signal was provided by the use of a "dummy" wing, similar to the one described in Reference (1). The "dummy" was placed in the linkage in the same manner as the wing and oscillated in a desired motion. The signals from the accelerometer and the dummy wing were then added and fed into a cathode-ray oscilloscope. By varying the output of the accelerometer with the voltage divider described above it was possible to almost exactly cancel out the dummy wing inertia signal. The best apparent setting of the voltage divider was chosen and the added signals were fed into the recording oscillograph. Records were taken at the best apparent voltage divider setting and at several values on either side. After these oscillograph records were developed it was possible to find one in which the resultant signal was zero. The voltage divider setting corresponding to this near perfect cancellation was then used throughout the entire series of tests.

If an indication of the average force or moment on a unit span of the wing was to be measured, it was necessary to have the sensitivities of all strain gages measuring that quantity equal. This was accomplished by applying an equal load to each supporting beam in turn, and adjusting the appropriate potentiometers in the equalizer box until the output for any one of the positions of loading was the same as for the others. This procedure was carried out for each of the lift, moment, and drag measuring elements.

Having equalized the sensitivities of the force measuring elements it was possible to calibrate. For lift, this was accomplished by placing a wooden platform over the dummy wing and loading it with weights of known value. Moment was calibrated by hanging known weights on a bar at the centerline of the rear elements, while drag

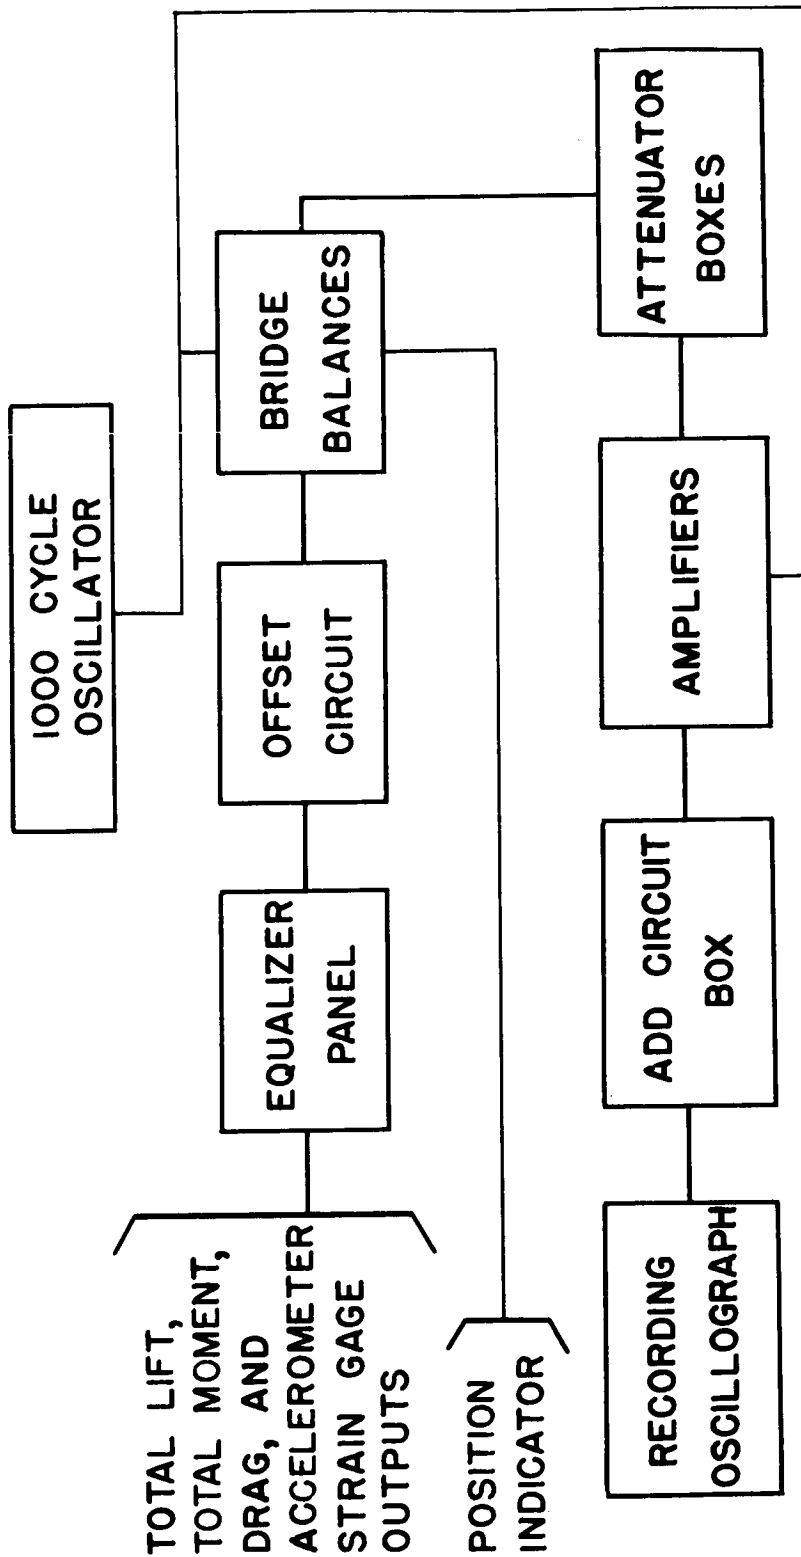

Figure 6
Block Diagram of Instrumentation.

MASSACHUSETTS INSTITUTE OF TECHNOLOGY
Department of Aeronautical Engineering

CONTRACT NO. NAW-5693

PAGE 15

calibration required a special rig of wire and pulleys so that loads could be applied in a horizontal plane.

In all these calibrations tare loads were taken into account and zero checks were made after every series of loads. A complete calibration of force measuring elements was made after every series of tests, and at all values of attenuation used during the tests.

The tunnel throat survey of Reference (1) indicates negligible variations in velocities across the test section, therefore no time was spent in making a similar survey, since conditions in general were almost identical. The tunnel calibrations were limited to a measurement of the velocity at the wing position in comparison with the velocity at the tunnel pitot tube position.

3.2(c) Wind-on Tests. The first wind-on tests were conducted to obtain the static airfoil characteristics of the three wing sections. These tests were run at 95 m.p.h., and consisted of a measurement of the lift and moment on the airfoils at intervals of angle of attack of approximately 3 degrees from the angle of zero lift up through the stall angle. The results of these tests are plotted in Figures 7, 8 and 9.

It was found that three men were required to run the systematic tests: one to operate the wind tunnel and oscillator, one to operate the instrumentation, and one to take data and check the steps of the instrumentation operator. Tests were carried out through the complete oscillator frequency range on each of the three airfoils at initial angles of 0, 6, 10, 12, 14, 18 and 22 degrees in pitch and translation.

The test procedure was about the same for all of the tests. With the wings installed between the end plates, and at the proper mean angle of attack, all necessary electrical adjustments were made and the tunnel was brought up to speed.

With the manometer set at 4.00 inches of alcohol the static lift force and moment signals were offset to as near zero airspeed position as possible, and the oscillator started and run up to the desired test frequency.

With the oscillator at test frequency the inertia and aerodynamic signals were adjusted separately to be just within the linear range of the amplifiers. The signals were then added and a record was taken.

The above procedure was repeated for each frequency, and then the tunnel power was shut off.

When the tunnel airspeed had reached zero, the offsets were all adjusted to the no load position, and zero records were taken at all values of attenuation used in the tests.

Readings of temperature were taken for each series of tests so that necessary corrections in velocities could be made.

CONTRACT NO. NAW-5693

PAGE 19

The procedure followed in each test is outlined again in the check-off list of Figure 10.

3.2(d) Systematic Tests. The tests carried out in this phase of the oscillator program are supplementary to the tests of Phase 6. The two types of motion considered in all tests are: (1) a pure pitching motion about the 37% chord with an amplitude of 6.08 degrees, and (2) pure translation with an amplitude of 0.9 inches.

The test results presented in Phase 6 included tests at angles of attack of 0, 6, 10, 14, and 18 degrees with frequencies of 4, 8, 12, and 16 cycles per second for each airfoil at each angle of attack.

The supplementary tests of this latest program were devoted entirely to the pure pitching motion described above. Their threefold purpose was to extend the range of $K(= \frac{ab}{V})$, to show trends at critical angles of attack not included in previous tests, and to show that small changes in Reynolds number would not affect the data to a large extent.

The supplementary tests included the following: (1) Tests of each airfoil at each of the angles of attack listed above at frequencies of 2 and 18 cycles per second. (2) Tests on each of the airfoils at mean angles of attack of 12, 16, and 22 degrees. (3) Tests on the intermediate airfoil at a mean angle of attack of 14 degrees at frequencies of 2, 4, 8, 12, 16, and 18 cycles per second, with velocities of 65, 80, 95 and 110 mph.

All tests except those of Item (3) above were conducted with an airspeed of approximately 95 mph.

3.2(e) Record Analysis. The analysis of records described below, consists of a measurement of peak amplitudes, apparent phase angles, and a harmonic analysis to determine net work per cycle, and fundamental amplitude and phase of moment in pure pitch. The oscillograph traces utilized in this analysis are lift, moment, and position. No data on drag are presented in this report since a preliminary analysis of drag data indicated a coupling of lift and drag in such a manner that at times a considerable error in drag was introduced. It appears, however, that drag forces are of little significance in the high angle of attack flutter problem, so that this omission is relatively unimportant.

The lift and moment inertia traces were not used directly in record analysis. The presence of these traces on the record served as a continuous check on general accelerometer performance and also provided a basis for spot checks which compared the measured accelerations with calculated values.

The lift and moment traces are representations of the oscillating aerodynamic lift and moment, so that measuring the amplitude of the lift or moment trace, and multiplying it by an overall calibration factor gives values of oscillatory lift or moment in pounds or inch pounds respectively. The coefficients of lift and moment which

are plotted in Plates 5 through 8 were calculated by use of the formulae:

$$C_L = \frac{L}{4qb(\text{Span})}$$

$$C_M = \frac{M}{4qb^2(\text{Span})}$$

The symbols " C_L " and " C_M " were used since they represent a magnitude without reference to wave form, whereas $\sqrt{R^2 + I^2}$ which was used in References (1) and (2), indicates the amplitude of a sinusoid.

The phase angle " ϕ " is defined in Reference (1) as the angle by which the force or moment leads the motion. This definition, however, is applicable only to a sinusoid. At large angles of attack, both the lift and moment traces tend to deviate from the pure sinusoids predicted by flutter theory. In cases where the wave form of the trace is not sinusoidal at the peak, no phase angles have been measured. In all cases, at angles of attack above 6 degrees, caution must be exercised in the interpretation of measured phase angle data. The plotted values of " ϕ " are averages of data taken from four cycles of each oscillation.

The positive directions of reactions, the peaks associated with maximum reactions, the location of peak angles of attack, and the distances measured to obtain phase angles are described in the diagram of Figure 11.

The work per cycle for a pure sinusoidal motion and reaction may be determined as follows:

$$W_{\text{Pitch}} = \oint M d\alpha = \pi \alpha_o M_o \sin \phi_M$$

$$W_{\text{Translation}} = \oint L dh = \pi h_o L_o \sin \phi_L$$

Since in general " M " and " L " were not pure sinusoids it was desirable to resort to a graphical integration to obtain work per cycle. One cycle of each record was chosen and integrated, and occasional spot checks were made to insure that a typical cycle was chosen. $\Delta\alpha$ and Δh were related to equal time increments in the manner illustrated by the

CONTRACT NO. NAW-5693

table of Figure 12, which also shows the graphical layout for the integration.

The axis directions of Figure 11 determine the sign of the work so that a positive sign indicates work done on the wing by the air stream, and a negative sign indicates work done on the air stream by the wing.

Since work per cycle is proportional to the magnitude of the imaginary component of the fundamental harmonic of moment, a similar integration from a plot of moment versus a motion 90° out of phase with the actual motion gives an area which is proportional to the real component. The ratio of work per cycle to this second area in work units is the tangent of the phase angle of the fundamental. From the equation above it can be seen that,

$$M_0 = \frac{W_{\text{Pitch}}}{\pi \alpha_0 \sin \phi_M}$$

where M_0 is the amplitude of the fundamental harmonic of the moment. Thus amplitude and phase angle of the fundamental harmonic of moment can be calculated.

The computation of the time-average values of lift and moment involves both measurements from the oscillograph records and the electrical offsets. First the distance from the mean line of the lift (or moment) trace to the zero airspeed trace was measured. This distance was converted to a force (or moment) by a calibration factor for the particular attenuation used. The recorded value of electrical offset terms of force (or moment) was added to the value obtained by measurement of distance on the oscillograph record to give the time average value of the reaction.

IV - ANALYSIS AND CORRELATION OF EXPERIMENTAL DATA

The experimental data discussed in the following pages of this section are the results of two different types of tests: (1) a series of flutter tests on wings of various properties held at high angles of attack in an airstream, and (2) tests involving the use of mechanical apparatus which is designed to impart a particular motion to an airfoil in a windstream.

The tests in the category of item (1) above have mostly been conducted in Europe, though two sets of American data are referenced later in this section. The data from such tests serves to describe the mechanisms producing flutter at high angles of attack in a very general way, so that forces and moments producing the oscillations cannot be directly related to the motions they produce. In order to relate reactions and motions the apparatus of item (2) above has been developed together with appropriate electrical measuring equipment.

Thus the aerodynamic reactions associated with a given motion may be accurately determined. The apparatus used in the M.I.T. tests is described in Section 3.1 of this report and the equipment used in the British tests is described in Reference (7).

Lift and moment in both pitching and translational motions are measured to obtain the M.I.T. data presented below. The British data involve only a measurement of moment in pitch or the out-of-phase component of moment in pitch.

The M.I.T. data has been taken with the value of Reynolds number near one million, while other investigators have used Reynolds numbers between 1.32×10^5 and 4×10^5 with the majority of the data from tests in a range below Reynolds numbers equal to 400,000.

Only very high Reynolds number data is applicable to aircraft wings, but the data taken with Reynolds number one million and below is in the proper range for aircraft propeller and turbine blades.

4.1 M.I.T. Data

The oscillograph records from 150 tests have been analyzed and are presented in graphical form in Plates 1 through 47, and in tabular form in Section IX.

The majority of the graphs use $K(=\frac{\omega b}{V})$ as the abscissa. In most of the tests, airspeed has been held constant so that 'K' is proportional to frequency. In cases where velocity has been varied, the velocities used are designated on the graph.

All data presented are within 5% of the true value. The maximum error in check calibrations is 2% and the instrumentation introduces an error no greater than 3%. These variations were allowed because of the nature of the data and the extreme amount of

MASSACHUSETTS INSTITUTE OF TECHNOLOGY
Department of Aeronautical Engineering

PAGE 26

CONTRACT NO. NAW-5693

time and expense required to maintain greater accuracy with the equipment used in taking data. Some data in the vicinity of the stall are not reproducible to the accuracy described above because the aerodynamic situation here is somewhat akin to a state of neutral equilibrium and the condition of the flow depends on tunnel flow inconsistencies as well as on the motion of the airfoil. These data, however, represent a very small part of the total, and data from angles near the stall may be accepted as representative of the situation existing unless it is otherwise noted on the graph or tabulation.

Some data have been obtained by a direct measurement from the oscillograph records of amplitudes and phase angles. Since the reaction traces are not sinusoids in many cases the measured values lose some significance. However, the basic trends of the data are well presented in this manner, and the method permits the analyst to cover a great deal of territory quickly.

Dimensionless coefficients of oscillatory force and moment and the phase relation of each of these with the motion have been measured directly from the oscillograph records and are plotted in Plates 1 through 8. It will be noted that for low angles of attack the experimental points compare quite well with the theory. At high angles of attack, however, the traces of force and moment are no longer sinusoids, so that direct measurement on the oscillograph records gives values which represent the peak value of an arbitrary wave form and the time interval between its peak and the peak of the motion. The high angle of attack values are plotted as phase angle and amplitude because the phase angles particularly have been found to be very close to the values obtained from harmonic analysis even where the trace of the reaction is far from sinusoidal. Further, both phase angles and amplitudes have been found to have the same general variation with K as the values calculated by the harmonic analysis method which involves considerably more time and expense.

Some points in the plates mentioned above have no curves faired through them. This may indicate that the points are from low angle of attack data where the reactions are essentially sinusoidal and hence should compare well with theory. Also in some instances at high angles of attack, experimental points have fallen very near theoretical curves and have been left without curves faired through them to avoid confusion.

The plots of work per cycle (Plates 9 through 15) and the plots of phase angles and amplitudes from harmonic analysis (Plates 16 through 21) are the results of the graphical integration described in the section on record analysis.

In the plots of work per cycle, the positive work range indicates that work is done on the wing by the airstream, while the negative work range indicates that work is done on the airstream by the wing. It can be seen that positive work corresponds to

MASSACHUSETTS INSTITUTE OF TECHNOLOGY
Department of Aeronautical Engineering

CONTRACT NO. NAW-5693

PAGE 27

negative damping so that in a free oscillation the amplitude would tend to increase if no other damping were present.

In the plots representing work per cycle in pure pitch the curves appear to describe a range of K in which positive work may be done. The graphs of Plates 9 through 11 show the lower limit of this positive work range and indicate that an upper limit exists by their tendency to assume a negative slope at higher values of K . The data compiled by Victory in Reference (6) and discussed in Section 4.2 show a continuation of this trend at values of K higher than those plotted in Plates 9 through 11.

In the plots representing work per cycle in pure translation, the curves all tend to remain in the negative work region. At very low values of K (much lower than were obtainable with the equipment available in this program) it appears that there may be a possibility of positive work. Such a possibility is discussed by Den Hartog in Reference (8) in connection with transmission line galloping. A further discussion of this possibility is contained in Section V.

The graphical integration described in the section on record analysis has been used to determine the fundamental amplitude and phase angle in the trace of moment due to pitching. This type of analysis parallels the analysis of Reference (9), so that it is possible to compare the trends of the two sets of data (see Section 4.2). Further, the trace of moment in pitch, while periodic, is farther from a pure sinusoid than any of the other reaction traces; and the fact that there is good agreement in the general trends of the data from the harmonic analysis and data measured directly from oscillograph records serves as an indication that the measured data (Plates 1 through 8) may be accepted as representing the trends to be expected from a harmonic analysis of the same basic data. A comparison of the phase angles of Plate 1 with those of Plates 16, 17 and 18 shows quite a remarkable agreement in order of magnitude and slope of the curves.

In general the coefficients of moment in pitch, plotted from the data of the harmonic analysis (Plate 19) are lower in value than the coefficients measured directly from the oscillograph records (Plate 5). This is to be expected since there are obviously higher harmonics which will contribute to the peak amplitude.

Plates 20 and 21 are respectively phase angle and amplitude of the fundamental harmonic of moment in pure pitch for various air speeds. These tests were made on the intermediate airfoil to find if the test data were severely affected by Reynolds number at high angles of attack. A mean angle of attack of 14° was used in all tests. This is the stalling angle of the intermediate airfoil at 95 mph.

Both of the above plates show some effects due to velocity changes. However, the trends of all curves are similar, and it is suspected that the primary reason for the

MASSACHUSETTS INSTITUTE OF TECHNOLOGY
Department of Aeronautical Engineering

PAGE 28

CONTRACT NO. NAW-5693

differences is the variation of stalling angle with Reynolds number.

Plates 22 through 25 are presented to indicate the possible values of time-average lifts or moments under oscillatory conditions and to compare these with steady state values. These coefficients could be used to calculate the total mean force or moment on the airfoils under oscillatory conditions.

Plates 22 and 23 are plots of the time average moment coefficients. Plate 22 shows the time average moment coefficients due to pitching. These vary considerably from the steady state coefficients even at mean angles well below the stall. This deviation occurs on all of the curves, so that it is too consistent to be attributed to experimental error. It seems that this variation must be due to a change in center of pressure caused by stalling of the flow where local angles of attack induced by the pitching motion are high. It is of interest to note that at 18° mean angle the curves of Plate 22 show that moment increases with K , while at 22° the opposite is true. The curves of Plate 23 show only relatively small deviations from the steady-state curves, and in general it seems that the stalling angles are almost the same with translatory oscillations as in the steady state case. At higher values of K , the maximum value of lift coefficient is slightly greater than the steady-state maximum value in all cases.

Plates 24 and 25 are plots of the time average lift coefficients in both pitching and translation. The data for the blunt wing in Plate 24 are somewhat incomplete since the zero records for 6 and 10 degrees were found in error for all values of K except .06. However, with the data from the other two airfoils and from both motions, these data seem to indicate that time average values of lift below the static stall may be assumed to be equal to the steady-state values without serious error. Near the steady-state stalling angle the time average values of lift may either exceed or be less than steady-state values for a pitching motion (Plate 24), but the lift continues near the maximum value for angles well above the steady-state stalling angle. The relation of lift coefficient to K in Plate 24 at high angles of attack is interesting in comparison with the relation of moment coefficient to K in Plate 22. As in Plate 22, at 18° mean angle the coefficient increases with K , but at 22° mean angle where the variation of moment coefficient with K is reversed, the variation of lift coefficient with K remains the same, thus indicating that between 18° and 22° mean angles the center of pressure has shifted.

The curves of Plate 25 for the blunt and sharp wings indicate that the lift in translation is somewhat higher than the steady-state lift, while the data for the intermediate wing shows about the same values for each. The lift coefficient increases with K in all cases, and the maximum values of lift coefficient are higher than those in

MASSACHUSETTS INSTITUTE OF TECHNOLOGY
Department of Aeronautical Engineering

CONTRACT NO. NAW-5693

PAGE 29

the steady-state case, although not necessarily occurring at the steady-state stalling angle.

All of the plates presented above give the results of various operations on the basic experimental data, and while they show correctly the trends and magnitudes of the quantities involved it is believed that the reader may gain a better physical feeling for the problem and a better understanding of what actually occurs during a cycle of oscillation if information such as that in plates 26 through 35 and 42 through 47 is presented him.

Plates 26 through 35 illustrate the variation of moment in pure pitch throughout a cycle of motion. The amplitude of the sinusoidal pitching motion is 6.08° in all cases and the pitching axis is at 37% chord.

Plates 26 through 28 illustrate the change with increasing mean angle of attack at a constant frequency. It will be noted that at 0° and 6° mean angle the moment traces a near elliptical shape quite similar to the path predicted in conventional flutter theory. The difference between the plotted figures and the elliptical path predicted by theory is due in part to the presence of hash on the oscillograph records and in part to the fact that the transcribed points were connected by straight lines rather than faired curves.

At 10° mean angle there is a definite break away from the ellipse at the maximum angle of attack, tending to reduce the negative work area enclosed in the loop. At 14° mean angle the top portion of the loop is similar in position and curvature to the ellipse predicted by theory, but the airfoil stalls sharply near the maximum angle of attack so that the loop is enclosed by a clockwise progression of the moment, and the enclosed area is thus a measure of positive work. It is this type of moment variation which causes negative damping at high mean angles of attack. At 18° mean angle the airfoil is always partially stalled as is indicated by the fact that the moment never reaches its steady state value. At 22° mean angle the airfoil is almost entirely stalled throughout the cycle and the work area has again become negative. The variations in moment are probably due principally to shifts in the center of pressure. The negative moment (Plate 28) does in fact indicate that the center of pressure has moved aft of the 37% chord line. The small positive work area near the minimum angle of attack indicates that the airfoil partially recovers from the stalled condition, and then stalls again almost immediately.

Plates 29 and 30 show the increase in enclosed area with increasing frequency for a pure pitching oscillation about a mean angle of 6° , all other conditions being held constant. This effect is predicted by flutter theory which is a good approximation to the

MASSACHUSETTS INSTITUTE OF TECHNOLOGY
Department of Aeronautical Engineering

PAGE 30

CONTRACT NO. NAW-5693

actual situation at this low angle of attack.

The loops described by the variation of the moment through a cycle assume various shapes depending on airfoil shape, mean angle, amplitude of motion and K . Plates 31 and 32 illustrate a variation of the frequency through the range previously described. Since this oscillation is partially in the stall the effect is different from the low mean angle case described above. It is evident from an examination of these curves, that the paths are composed of a part in which the moment attempts to follow the low angle of attack slope of the moment curve, and another portion in which stall and recovery occurs. For low frequencies the recovery is made before the minimum angle is reached, but at the highest frequency complete recovery from the stall does not occur until after the minimum angle is passed. Plates 33 and 34 show the same general variation with frequency as Plates 29 through 32, but at a different mean angle.

Plate 35 is included to show types of moment variations not shown in other plates. It can be seen that in general (or at least in the case of these three airfoils) with increasing mean angle of attack the moment through a cycle describes (1) an ellipse as predicted by theory, (2) a near ellipse except for a concavity on its upper side, (3) a figure eight shaped curve in which one loop indicates negative work and the other indicates positive work, (4) a loop which indicates all positive work, (5) another figure eight similar to (3) and, (6) a loop which indicates all negative work when the airfoil is at a mean angle high enough that it never recovers from the stalled condition.

Several investigators notably Reid in Reference (10) have noted that in a pitching oscillation the stall may occur at an angle of attack considerably above the static stalling angle. The amount which the oscillatory stalling angle exceeds the static stalling angle is dependent on a number of factors among which are K , $\frac{d\alpha}{dt}$, airfoil shape, and amplitude of oscillation. Plates 36, 37, and 38 are graphs showing the variation of $\delta\alpha(\alpha_{(Stall)} - \alpha_{(steady\ state\ stall)})$ with K for the three airfoils of the tests at various mean angles and for an amplitude of oscillation of 6.08° . Plates 39, 40, and 41 plot $\delta\alpha$ versus $\dot{\alpha} (= \frac{d\alpha}{dt})$ at stall for the same conditions. On all of these plots the curves are faired through the points in order of increasing frequency and the upper points at $\dot{\alpha} = 0$ are calculated on the assumption that at a sufficiently high frequency the airfoil will not stall before its maximum pitching amplitude is reached. The data required for all of the $\delta\alpha$ plots was obtained by measuring the oscillatory stalling angles from plots similar to those of Plates 26 through 35.

Plates 42 through 47 illustrate the variation of lift in pure translation throughout a cycle of motion. The amplitude of the sinusoidal translatory motion is 0.9 inches in all cases.

AERO-ELASTIC AND STRUCTURES RESEARCH

MASSACHUSETTS INSTITUTE OF TECHNOLOGY
Department of Aeronautical Engineering

CONTRACT NO. NAW-5693

PAGE 31

Plates 42 and 43 illustrate the effect of increasing mean angle of attack for the airfoils in a pure translatory motion. It can be seen that the loops enclose very nearly equal areas except for the case where the airfoil is completely stalled. The change in size of these work loops for a given airfoil is dependent upon $K(=\frac{\omega b}{V})$ in addition to the mean angle, hence the plots of work per cycle in translation, (Plates 12 through 14) reveal a more complete picture. The more general trend in translation is an increase in negative work per cycle up to a mean angle approximately equal to the static stalling angle and then a sharp decrease in negative work per cycle for angles above the static stall.

Plates 44 and 45 illustrate the effect of increasing frequency at a constant mean angle of 10° . As in the case of pitching motion, the enclosed area increases in size with frequency. This seems to be a general tendency for airfoils in translational motion.

Plates 46 and 47 show comparative data for the three airfoils used in the tests.

Plates 40 through 55 were chosen as typical examples of the oscillograph data analyzed and presented in this section, and where possible these plates are actually the basic data which is presented as the variation of lift or moment through a cycle of oscillation in Plates 26 through 35 and 42 through 47. These Plates are presented to show in a qualitative way the variation of the reactions with time and the order of magnitude of the extraneous reactions and oscillations encountered. The additional points described below will be evident after an examination of the plates by the reader.

Plates 48 through 50 are for a harmonic pitching motion. In the four pictures of Plate 48 one can see the pure sine wave at 0° , a slight distortion of the sine wave at 10° , and at 18° a wave which is periodic but bears very slight similarities to a sine wave.

Plate 49 illustrates the differences in stalling characteristics and in recovery from stall for the three airfoils shown in Figure (4).

The records of Plate 50 show the effect of increasing frequency on the sharp nosed airfoil of Figure (4).

Plates 51 through 53 are for a harmonic translatory motion. Plate 51 shows the effect of increasing mean angle on the intermediate airfoil. Plate 52 shows differences in airfoils at a mean angle of 10° and a frequency of approximately 8 c.p.s., while Plate 53 shows the effect of increasing frequency on the sharp airfoil. It will be noted that in general the differences in corresponding records for translatory motion are much less than for pitching motion.

Plate 54 shows the record obtained from the blunt airfoil at an angle very near the static stalling angle. This record is not periodic, apparently indicating a condition of partial stall all through the cycle of motion with the amount of stall not directly related to induced angle but probably more a function of tunnel flow inconsistency.

Plate 55 is another record taken very near the static stalling angle. It can be seen that the wing is stalled during some cycles and unstalled during others. The records of Plates 54 and 55 are indications of the poor degree of reproducibility of data at angles near the stall as mentioned earlier in this section. This situation occurs more frequently in translatory motion than in pitching motion, and its effects are more pronounced in translation. It is apparent that the solution to this problem is a tunnel with an absolutely uniform flow.

4.2 Correlation with Experimental Data from Other Sources

Other experimental data which have been gathered on airfoils oscillating at high angles of attack may be divided into two general types: (1) critical speeds obtained in a manner similar to that used in conventional flutter tests, except that the airfoil is placed at an initially high angle of attack in the airstream, and (2) tests which measure the oscillating aerodynamic moment in pure pitch in a manner similar to that used in the M.I.T. tests, but which neglect other reactions and motions. The tests under the category of item (1) above were carried out for the most part several years ago. Several investigators have contributed to these data; Studer and Kaufman whose work is summarized by Victory in Reference (6), Rauscher in Reference (4), and Bollay and Brown in Reference (9) being the most noteworthy.

An even larger number of experiments has been made in the category of Item (2) above. Victory in Reference (6) describes tests in which only the out-of-phase component was measured, and Bratt and Scruton in Reference (7) plot the path of moment through a cycle of oscillation much in the same manner as is done in this report.

Bratt and Wight in Reference (9) have been able to measure both the in-phase and out-of-phase components of moment, thus making possible the computation of vector amplitude and phase angle of the fundamental.

One further interesting reference is available which falls into neither of the categories listed above. Reference (12) by Bratt, Wight, and Chinneck is an investigation of aerodynamic damping in pure pitch as affected by initial angle and angular amplitude of oscillation.

4.2(a) High Angle of Attack Flutter Tests

Rauscher and Studer were among the first experimenters to show the sharp drop in critical speed as angle of attack is increased toward the stall. Studer's investigation showed, and since then other investigators have shown, that for low values of frequency parameter and drop in flutter speed may be as much as 60% of the classical flutter speed.

MASSACHUSETTS INSTITUTE OF TECHNOLOGY
Department of Aeronautical Engineering

CONTRACT NO. NAW-5693

PAGE 33

However it has also been shown that as frequency parameter is increased the percentage drop in flutter speed decreases so that at very high values of K the classical and stalling flutter speeds tend to approach a common value.

Studer (Reference 5) was able to obtain some interesting results by varying the mass and geometrical properties of his wing. A minimum stalling flutter speed was found to occur when the elastic and gravity axes were coincident so that there was no inertia coupling. A critical speed below even this minimum was obtained by restraining the wing from translatory motion and allowing only freedom in pitch.

Studer also varied the bending torsion frequency ratio, and found that the critical speed in stalling flutter was quite insensitive to such variations. In all of the cases investigated in Europe the flutter motion was observed to be predominantly a pitching oscillation even though the same physical configuration had primarily a translatory motion in classical flutter. However, Bollay and Brown at Harvard observed a stalling flutter of a solid dural propeller section in principally the first bending mode. The critical speed was 127.5 m.p.h. as compared with a classical flutter speed of 900 m.p.h. so that it is almost certain that the rather violent vibrations were actually stalling flutter. It is possible that the first bending mode of the blade was equivalent to a translation plus an in phase rotation about an axis forward or aft of the blade, but there are insufficient data to really fix the mode of flutter in Reference (11). Bollay and Brown differentiated between the usual stall flutter and the excitation associated with Karman vortices. Their results showed that since the Karman vortex frequency was directly proportional to velocity, moderate vibrations built up at airspeeds where vortex frequency coincided with a natural frequency of the wing. These vibrations however were much less violent than the oscillations described above and the reduced frequency for Karman vortex excitation was about three times that for stall flutter. These same experimenters made a number of tests on another wing, and their results are used as a basis for some of the computations and text in Section V.

4.2(b) Measurement of Aerodynamic Reactions

A large part of the data in Reference (6) which includes the work of Bratt and Scruton (Reference 7) has been replotted against the same variables used in the presentation of M.I.T. data.

It can be seen that the M.I.T. and the British data cannot be made to compare quantitatively since there is no theoretical correction such as that described in Reference 2, which can be applied to account for changed pitching axis position. Further the airfoil shapes used in obtaining the British data are different from the airfoils

described in this report, and the Reynolds numbers are widely different. Also due to the low airspeeds used in the British tests considerably higher values of the frequency parameter were obtainable, so that the two sets of test data do not cover the same range.

Plates 56 through 61 are taken from Reference (6), and it is possible to obtain rather good qualitative comparisons with M.I.T. test data if $\Delta\alpha$ is defined as the angular interval between the mean angle and the steady-state stalling angle of the airfoil (positive when α_i is greater than the steady-state stall), and this parameter is used as a basis of comparison. By using data from the M.I.T. tests for the low K range and the British data for the higher K range, and the highest angle of attack range, Figure 13 was constructed using parts of plates 9 through 11 and 56 through 61. This figure shows approximately the way in which work per cycle (or aerodynamic moment) varies with K and α . First for low angles of attack the curves of work per cycle versus K remain negative and near the theoretical curves, gradually approaching zero work as $\Delta\alpha$ approaches zero. Near $\Delta\alpha$ equal to zero a positive work area appears at very low values of K . As $\Delta\alpha$ is further increased the maximum value of positive work is increased and the range of positive work is narrowed but continues to move to higher values of K .

Reference (6) has summarized the results of several investigations into the effect of Reynolds Number on the out-of-phase component of aerodynamic moment. The curves and tabulated data in this summary show that for high Reynolds Numbers (above 2×10^6) and moderately high values of frequency parameter (above 0.5) the effect of angle of attack on the out-of-phase component of aerodynamic moment is small. Thus in this range a pure pitching oscillation with a conventional rotational axis position would be damped. Bratt and Wight in Reference (9) devote a considerable portion of their work to an investigation of the effects of aspect ratio, which is beyond the scope of this report. However these investigators were able to measure both components of the oscillatory aerodynamic moment, so that their data can be plotted in a manner similar to the M.I.T. data. Plate 62 is a plot of work per cycle versus K . These data compare quite favorably with M.I.T. data if the basis of comparison is $\Delta\alpha$ rather than α_i .

Plate 63 is a plot of oscillatory moment coefficients and Phase angles and it can be seen that these curves are quite similar to some of the data plotted from the M.I.T. tests. Theoretical curves are also plotted on Plate 63 and phase angles particularly can be seen to agree quite well with theory for low angles of attack.

All of the data taken in Great Britain measures the oscillating aerodynamic moment less the still air inertia and damping forces. In Reference (9) a coefficient to account for still air damping has been obtained experimentally, but none of the plates described above have such a correction applied. However in most cases the effect of

CONTRACT NO. NAW-5693

PAGE 35

FIGURE 13
TYPICAL VARIATION OF WORK PER CYCLE WITH K AND ΔCC

MASSACHUSETTS INSTITUTE OF TECHNOLOGY
Department of Aeronautical Engineering

PAGE 36

CONTRACT NO. NAW-5693

this damping is small enough that the general trends of the data are preserved.

4.2(c) Effect of Oscillation Amplitude.

In all of the British references it has been observed that the reactions on an airfoil oscillating at high angles of attack are functions of the amplitude of the oscillation as well as Reynolds Number, frequency, velocity and initial angle of attack.

Especially in Reference (9) was this particular phase of the problem investigated. This series of experiments definitely established the fact that there are amplitude effects at high initial angles of attack, but for any given set of conditions only two amplitudes of oscillation were studied so that no curves of aerodynamic reactions versus oscillation amplitude can be plotted.

The authors of Reference (12) attack the problem of amplitude effects in a different manner than the other experimenters. Their thesis is that for any initial angle of attack there is some magnitude of angular deflection which can cause partial stalling of the flow and thus cause negative damping of the motion. The mechanical apparatus used in this series of experiments was an airfoil restrained against translational motion and spring mounted in pitching so that if it were deflected and released, a pure pitching oscillation resulted. At various values of reduced frequency, tests were run in which the airfoil was deflected thru larger and larger angles from a given initial angle of attack until an undamped pitching oscillation was observed on release of the airfoil. Thus a series of critical angular amplitudes were obtained, below which oscillations were damped and above which the oscillations tended to diverge. Plate 64 is a plot of such data taken directly from Reference (12). These curves show a stable range at low and at very high angles of attack, and a range of instability in between. A similar effect (with a constant angular amplitude) may be observed by referring to Plates 9, 10, and 11, and noting that with increasing initial angle of attack the curves move into the positive work range and then back into the negative work range.

PAGE 37

V - STALL FLUTTER ANALYSIS

The term 'stall flutter' is usually associated with a periodic self-excited vibration of an 'airfoil' with definite mass and elastic properties in a flow which is separated during part or all of the motion. The basic difference between 'classical flutter' and 'stall flutter' is in the character of the flow. As pointed out by Victory in Reference (6), stall flutter is not likely to occur on conventional airplane wings, but it does occur on propeller blades and turbine blades and some basis for predicting stall flutter or at least some knowledge of its characteristics would be very helpful. Of course in these applications three-dimensional and cascading effects further complicate the picture.

The experimental evidence of stall flutter has been obtained for the most part under controlled laboratory conditions where the flow is two-dimensional and the airfoil is rigid and supported on springs. Even for these tests, however, no adequate method of prediction has been evolved.

This problem of prediction by analytical means can probably best be approached by examining the additional complexity introduced by the stalling of the airfoil. Basically the mass and stiffness properties of the wing are unchanged but a new variable, the initial angle of attack α_i , has been introduced into the determination of the aerodynamic derivatives. Perhaps a better form for this new variable is something like the $\Delta\alpha (= \alpha_i - \alpha_{stall})$ used in Plates 36 through 41. Regardless of the form, however, the problem becomes extremely complex because the aerodynamic derivatives can no longer be simply superimposed as in classical flutter theory; that is, the aerodynamic result of a pitching motion can not be separated from that of a simultaneous translatory motion. There is the further effect that even in a pure motion the introduction of the new angle of attack variable automatically requires consideration of the large effects of such factors as Reynolds Number and airfoil shape.

Thus an exact mathematical formulation of the problem is out of the question at present and the attack must be made along empirical lines. Unfortunately only a small amount of empirical data has been published although a number of general characteristics of the usual stall flutter can be deduced from these tests. As the angle of attack is raised through the stall region and the flow is stalled during larger and larger parts of the cycle of vibration,

MASSACHUSETTS INSTITUTE OF TECHNOLOGY
Department of Aeronautical Engineering

PAGE 38

CONTRACT NO. NAW-5693

1. the flutter speed drops severely,
2. the flutter frequency rises slowly toward the torsion frequency of the wing, and,
3. the motion appears to become predominantly pure torsion although the axis of rotation is not in general the elastic axis.
4. Usually the flutter speed reaches a minimum and then rises again as the flow becomes completely stalled.

A study of these general characteristics has suggested the following plan of attack which is based on proceeding from the comparatively firm ground of classical flutter into the realm of stalled flows.

1. Attempt to take initial angle of attack into account by modifying the existing classical theory by whatever means suggest themselves through experience or intuition. Preferably these analyses should automatically reduce to the classical case at low initial angles of attack.
2. Determine which general kinds of modification produce the trends which have been observed in actual cases of stall flutter.
3. Attempt to correlate these findings with existing aerodynamic derivative data in the hope of discovering which aerodynamic terms play a dominant part in stall flutter.
4. Try to predict the possible variations of these critical terms using airfoil data ordinarily available.

This plan of course is aimed at the kind of stall flutter in which the angle of attack does not exceed the steady-state stall angle by more than eight or ten degrees.

5.1 Den Hartog's Simplification

Den Hartog (Reference 8) shows that one type of transmission line galloping is actually a stall flutter where the angle of attack of the ice-coated cable is of the order of ninety degrees. For an analysis of this motion it would of course be foolish to try to modify classical aerodynamic terms rather than make an attempt at estimating the aerodynamic derivatives in the completely stalled flow. Since the frequency of the galloping is only about one cycle per second ($K \sim 0.1$), Den Hartog, as a first attempt, works only with an assumed static or steady state lift curve. Considering the changes in angle of attack to be induced by the vertical motion he shows that the motion is negatively damped on the negative slope portion of the lift curve. Although an excellent qualitative discussion it is suggested that if quantitative answers to this problem are

MASSACHUSETTS INSTITUTE OF TECHNOLOGY
Department of Aeronautical Engineering

CONTRACT NO. NAW-5693

PAGE 39

desired the rotation of the transmission line can not be overlooked. It seems certain that, with the very low torsional stiffness of the long span of cable, the combined effect of the mass unbalance caused by the ice formation and the aerodynamic moment about the cable axis will produce changes in angle of attack of the same order of magnitude as those induced by the vertical motion.

5.2 Victory's Use of Experimental Data

Turning to the more usual type of stall flutter, Victory in Reference (6) follows the first three steps of the outlined plan of attack to show the dominant effect of the torsional damping parameter. This parameter j_3 , is equivalent to

$$\frac{\pi}{4} \left[\frac{1}{2}(\frac{1}{2} - a) - (\frac{1}{4} - a^2)F - (\frac{1}{2} + a) \frac{G}{K} \right]$$

in the usual expression for aerodynamic moment in the vortex sheet theory,

$$M = -4\pi q b^2 \left\{ \left[\frac{a k^2}{2} - (\frac{1}{2} + a) i K C \right] \frac{h}{b} + \left[\frac{1}{2} (i k (\frac{1}{2} - a) - k^2 (\frac{1}{8} + a^2)) - (\frac{1}{2} + a) (1 \times i k (\frac{1}{2} - a) C) \right] \alpha \right\}$$

It had long been suspected by the British that the reduction in flutter speed near stalling angles of attack was caused by a reduction of aerodynamic torsional damping. Thus Victory decided to try modifying the classical theory by varying only the parameter j_3 .

Fortunately experimental measurements of j_3 had been made at the National Physical Laboratories for an airfoil which was very similar to one used by Studer (Reference 5) for actual stall flutter tests under almost identical conditions. In each case the symmetrical airfoil had a reference axis at one-half chord and was tested through about the same Reynolds Number and frequency parameter ranges. Thus, by this happy circumstance, it was possible to substitute measured values of j_3 into the modified classical theory and then check the results against comparable stall flutter tests. Inasmuch as the agreement between calculated and experimental flutter speeds is very good, an examination of the procedure is probably well worthwhile.

The series of tests by Studer for which calculations were made had a common value of torsional frequency and six different bending frequencies so that the range of

MASSACHUSETTS INSTITUTE OF TECHNOLOGY
Department of Aeronautical Engineering

PAGE 40

CONTRACT NO. NAW-5693

frequency ratio $(\frac{\omega_c}{\omega_b})$ was from 1.06 to 2.12. Flutter calculations were made for these conditions for values of j_3 ranging from 0 to 1.0 so that plots of flutter speed, frequency and frequency parameter λ_c ($\lambda_c = 2k$) versus j_3 could be constructed. These plots have been reproduced as Plate 65. A dotted curve of the classical variation of j_3 with λ_c has been superimposed on the last-mentioned Plate to show the amount of variation of torsional damping required at any value of the frequency parameter to produce flutter. The intersection of this curve with each of the solid lines indicates the value of j_3 corresponding to the classical flutter solution for each frequency ratio. These values of j_3 then determine the flutter speeds and frequencies as marked by circles on Plate 65(a).

In order to obtain the semi-empirical stall flutter points, Victory plotted the six theoretical curves of λ_c versus j_3 on the same sheet as the N.P.L. (j_3, λ_c) curves, where they cut most of the experimental curves at least once. At these points of intersection the correct experimental correspondence exists between j_3 and λ_c for the particular angle of attack at which the experimental curve was plotted. The flutter speeds corresponding to these values of j_3 were then obtained from Plate 65(a). The agreement between these calculated and Studer's experimental flutter speeds is quite good, especially for the larger frequency ratios where the flutter speed does not vary so sharply with j_3 . As mentioned by Victory the calculated flutter speeds have their sharp drop at a slightly lower angle of attack than the experimental speeds largely because the static stalling angle of Studer's wing is about 2.5° higher than the N.P.L. wing. If the speeds had been plotted against $\Delta\alpha (= \alpha_i - \alpha_{stall})$ rather than α_i , this difference would disappear.

Thus it appears that the decrease, although not necessarily the disappearance, of torsional damping is an important, almost predominant, factor in the stall flutter of this particular wing.

In an attempt to extend these findings to another range of parameters, some theoretical points similar to those of Plate 65 have been calculated for Wing II tested by Bollay and Brown (Reference 11) and used by Mendelson (Reference 13) in his analytical approach. The results of these calculations appear in Figure 14 along with results stemming from Mendelson's analysis.

5.3 Mendelson's Modification of Classical Theory.

A somewhat different approach to the stall-flutter problem was employed by Mendelson in Reference 13. Following to some extent the plan of attack outlined earlier in this section, the classical theory was modified in the stall range to take into account a suspected aerodynamic hysteresis or lag. As stated by Mendelson, 'The assumption was

made that the absolute magnitude of the oscillatory aerodynamic forces and moments are the same at the stall as at zero angle of attack but that the vector magnitudes of these forces and moments are changed, this change being caused by the lag of the aerodynamic damping and restoring forces behind the velocities and displacements at stall, thus giving rise to a hysteresis effect.' Denoting this lag by the angle ϕ , the classical expressions for lift and moment become,

$$\frac{L}{4qb} = -\pi \left(-\frac{K^2}{2} - KG + iKFe^{-i\phi} \right) \frac{h_0}{b} e^{i\omega t}$$

$$- \pi \left(\frac{aK^2}{2} - K(\frac{1}{2} - a)G + Fe^{-i\phi} + i \left[\frac{K}{2} + G + K(\frac{1}{2} - a)F \right] e^{-i\phi} \right) \alpha_0 e^{i(\omega t - \beta)}$$

$$\frac{M}{4qb^2} = -\pi \left(\frac{aK^2}{2} + K(\frac{1}{2} + a)G - iK(\frac{1}{2} + a)Fe^{-i\phi} \right) \frac{h_0}{b} e^{i\omega t}$$

$$- \pi \left(-\frac{K^2}{2} \left(\frac{1}{8} + a^2 \right) + K \left(\frac{1}{4} - a^2 \right) G - (\frac{1}{2} + a)Fe^{-i\phi} \right)$$

$$+ 'i \left[-(\frac{1}{2} + a)G - K \left(\frac{1}{4} - a^2 \right) F + \frac{K}{2} (\frac{1}{2} - a) \right] e^{-i\phi} \alpha_0 e^{i(\omega t - \beta)}$$

Substituting these expressions in the usual bending-torsion flutter relations,

$$- m\omega^2 h_0 e^{i\omega t} - S_\alpha \omega^2 \alpha_0 e^{i(\omega t - \beta)} + C_h h_0 e^{i\omega t} - L = 0$$

$$- I_\alpha \omega^2 \alpha_0 e^{i(\omega t - \beta)} - S_\alpha \omega^2 h_0 e^{i\omega t} + C_\alpha \alpha_0 e^{i(\omega t - \beta)} - M = 0$$

expanding the determinant of the coefficients of h_0 and $\alpha_0 e^{-i\beta}$ and separating into a real and an imaginary equation there result two quadratics in $\left(\frac{\omega_t}{\omega}\right)^2$ with coefficients involving K and ϕ . These may be written,

MASSACHUSETTS INSTITUTE OF TECHNOLOGY
Department of Aeronautical Engineering

PAGE 42

CONTRACT NO. NAW-5693

$$\left(\frac{\omega t}{\omega}\right)^2 = F_1(K\phi) = F_2(K\phi)$$

If the properties of a given wing are substituted in F_1 and F_2 , the equation can be solved for K for a given ϕ by finding the intersections of F_1 and F_2 plotted against K .

This was done by Mendelson for the wing used by Bollay and Brown (Reference 11). For zero aerodynamic lag, that is for ϕ equals zero, the solution gives the classical flutter speed of 79 miles per hour. For increasing ϕ the flutter speed drops almost linearly to about 30 mph at a ϕ of 55 degrees. Encouraged by this result Mendelson proceeded to relate this change in ϕ to the steady-state lift curve.

A closer examination of his answer, however, would have produced disquieting results. The drop in flutter speed is also accompanied by a decrease in flutter frequency which is contrary to the Bollay and Brown tests, to the usual experimental results and to Victory's predictions. It also appears that the assumed values of aerodynamic lag ϕ are, especially for moment due to pitch, opposite in sign to the experimentally observed behavior in forced motion discussed in Section IV. For the assumed change in vector but not absolute magnitudes, the only way for Mendelson's ϕ to follow the trends indicated experimentally is to take on negative values, that is, values less than 360 degrees.

This second observation indicates that perhaps Mendelson was looking for the equality between F_1 and F_2 for the wrong range of ϕ . To check this observation a calculation was made at a reduced frequency of 0.30 which corresponds to a ϕ of 35 degrees on Mendelson's curve. As can be seen in Plate 66, another intersection exists for this K at $\phi = 351^\circ$ which yields a higher flutter frequency but lower flutter speed than for the classical case. The frequency is somewhat higher than might be expected as shown on Figure 14 but the trend is correct.

Since observed stall flutter oscillations are usually described as predominantly pure pitching motions a check was made of amplitude ratio and phasing between the motions for the classical case and for ϕ equal to 23, 35 and 351 degrees. A ϕ of 23 degrees corresponds to a calculated flutter speed equal to the experimental speed measured at an initial angle of attack of 11.2 degrees. Values of ϕ of 35 and 351 degrees correspond to a calculated flutter K very nearly the same as the experimental K for the same test. The results as shown on Figure 14 indicate that for all three values of ϕ the motion is predominantly pitch although about quite different axes. For β of 10.7 degrees ($\phi = 35$ degrees) the effective axis of rotation is about half a semi-chord length ahead of the elastic axis; for β of 172.4 degrees ($\phi = 351$ degrees) the effective axis is about

MASSACHUSETTS INSTITUTE OF TECHNOLOGY
Department of Aeronautical Engineering

CONTRACT NO. NAW-5693

PAGE 43

the same distance behind the elastic axis. It is unfortunate that Bollay and Brown did not record either phasing or effective axis of rotation.

A basic difference between Mendelson's and Victory's approaches is the number of terms in the classical expressions which are modified in the stall range. Victory modifies only one critical term, the torsional damping. Mendelson applies his factor to a majority of the aerodynamic terms. In order to compare the results of the two procedures calculations were made at a reduced frequency of 0.3 for the Bollay and Brown wing using Victory's modification. In addition calculations were made at the same reduced frequency applying Mendelson's 'corrected' factor ϕ only to moment in pitch. The results, as shown in Figure 14, show that for this case the additional modifications imposed by Mendelson had a very small effect, although none of the answers check very well with the experimental values.

This latter discrepancy may indicate that another aerodynamic term should be modified in an as yet untried manner although it is possible that small errors in wing properties may be greatly magnified in the calculations because the frequency ratio is quite near unity. To investigate which aerodynamic terms play an important part in the critical balance at flutter, vector plots have been constructed to illustrate some of the solutions. As shown on Plate 67 the plots are referred to a unit α vector with separate vectors for lift and moment due to pitch about the elastic axis and for lift and moment due to translation. Lift and moment are plotted in such a way that the components of the moment vectors perpendicular to α are a measure of the work per cycle in pitch and the components of the lift measured perpendicular to h multiplied by the amplitude ratio $\frac{h}{ba_0}$ are a measure of the work per cycle in translation.

It appears that in the cases corresponding to stall flutter the energy balance is governed by the torsional damping, the lift due to pitch, the phasing between the lift due to pitch and the translational motion, and the amplitude ratio. Thus the aerodynamic reactions resulting from the translation are very small but the work per cycle associated with translation combined with lift due to pitch is a very important part of the energy balance. On this basis a more complete evaluation of the available data on lift due to pitch seems to be desirable in order to determine what other modification of the classical theory is appropriate. Variation of torsional damping is important, perhaps predominant, but is not the complete answer to stall flutter prediction.

5.4 Haley's Prediction of Aerodynamic Moment

Apparently, then, it is possible to predict to some extent the trends of stall flutter for a particular configuration if experimental oscillatory data, especially for moment in pitch, are available. The data, however, must be for the correct airfoil shape, Reynolds Number range, and reduced frequency range.

This data, of course, is hardly ever available and is very expensive to obtain experimentally. Thus a very necessary step in an adequate prediction technique concerns the deduction of this information from steady-state data normally available. This available data should contain in so far as possible the effects of airfoil shape and Reynolds Number.

Mendelson (Reference 13) attempted to correlate his phase lag ϕ with the changes in slope of the steady-state lift versus angle of attack curve. This type of correlation may be a fair first approximation for relating a correction to the theory to the characteristics of the airfoil section but it makes no allowance for the variation in ϕ with reduced frequency which definitely does occur.

Haley in Reference 14 attempts in the case of moment in pitch to use the steady-state moment versus angle of attack curve to predict the actual variation of moment in the stall range including the effects of reduced frequency and amplitude of oscillation. Actually all of his work was done for one airspeed but, as will be shown, the method can be generalized quite easily. Some intelligent guessing and experience is needed to get reasonable and useful results by this method but the end result could quite possibly be a satisfactory set of torsional damping versus reduced frequency curves for a useful range of angles of attack.

Since the original paper is not generally available, a detailed and somewhat improved development is presented here.

If at a given airspeed and instantaneous angle of attack the actual value of moment coefficient (or moment) differs from the steady-state value by an amount ΔC_m , a possible assumption is that the rate of return of C_m to the steady-state value is proportional to ΔC_m . This can be written simply,

$$\frac{dC_m}{dt} = - \frac{\Delta C_m}{T_r} \quad (1)$$

where T_r can be thought of as a characteristic time. Equations of this form describe many simple physical systems whose response to a step function is a simple exponential governed by the characteristic time or time constant T_r .

MASSACHUSETTS INSTITUTE OF TECHNOLOGY
Department of Aeronautical Engineering

PAGE 46

CONTRACT NO. NAW-5693

As might be expected, however, this equation is a little too simple to describe the variation of moment.

In comparing the predictions of this equation with the known behavior of moment during oscillations at angles of attack below the stall it was found that T_r is different for different frequencies of oscillation and that the very simple definition of ΔC_m is not adequate. An arrangement similar to the static and dynamic load line concept in electronics was found to be necessary for handling oscillations at various initial angles and frequencies. Thus ΔC_m is now redefined (Figure 15) as

$$\Delta C_m = C_m - (C_{m_i} + \lambda \alpha) \quad (2)$$

where C_{m_i} is the value of C_m given by the steady-state characteristic for the initial angle of attack α_i ,

λ is the 'dynamic' slope of moment versus angle of attack, and

α is the instantaneous angle of attack referred to α_i and is usually written

$$\alpha = \alpha_0 e^{i\omega t}$$

Using the new definition of ΔC_m together with the basic differential equation,

$$\frac{dC_m}{dt} = - \frac{\Delta C_m}{T_r} \quad (1)$$

the following equations are obtained.

$$\frac{d(\Delta C_m)}{dt} + \frac{\Delta C_m}{T_r} = - \lambda \frac{d\alpha}{dt}$$

$$\frac{d}{dt} (C_m - C_{m_i}) + \frac{1}{T_r} (C_m - C_{m_i}) = \frac{\lambda}{T_r} \alpha$$

Assuming in each case a constant frequency oscillation $\alpha = \alpha_0 e^{i\omega t}$,

$$\Delta C_m = - \frac{\lambda \alpha_0 \omega T_r}{1 + (\omega T_r)^2} (\omega T_r + i) e^{i\omega t} \quad (3)$$

MASSACHUSETTS INSTITUTE OF TECHNOLOGY
Department of Aeronautical Engineering

CONTRACT NO. NAW-5693

PAGE 47

$$C_m = C_{m_i} + \frac{\lambda \alpha_0}{1 + (\omega T_r)^2} (1 - i\omega T_r) e^{i\omega t} \quad (4)$$

The classical expression for moment due to pitch is (Reference 15),

$$C_m = C_{m_i} + \frac{\pi}{2} \alpha_0 e^{i\omega t} \left\{ [2(\frac{1}{2} + a)F - 2(\frac{1}{4} - a^2)KG + (\frac{1}{8} + a^2)K^2] \right. \\ \left. + i [2(\frac{1}{2} + a)G + 2(\frac{1}{4} - a^2)KF - (\frac{1}{2} - a)K] \right\}$$

Equating the two expressions for C_m ,

$$\omega T_r = - \frac{2(\frac{1}{2} + a)G + 2(\frac{1}{4} - a^2)KF - (\frac{1}{2} - a)K}{2(\frac{1}{2} + a)F - 2(\frac{1}{4} - a^2)KG + (\frac{1}{8} + a^2)K^2} \quad (5)$$

$$\lambda = \frac{\pi}{2} \{2(\frac{1}{2} + a)F - 2(\frac{1}{4} - a^2)KG + (\frac{1}{8} + a^2)K^2\} \{1 + (\omega T_r)^2\} \quad (6)$$

Thus it appears that the simple assumed differential equation is adequate for unstalled flow if (ωT_r) and λ are determined for a given reduced frequency from the above relations.

The fact that the product ωT_r is the important parameter rather than T_r alone suggests that a better formulation is possible. The product ωT_r can be considered as a frequency ratio which compares the frequency of the motion to a frequency which is characteristic of the aerodynamic moment at the given airspeed. By suitable juggling it can also be written that

$$\omega T_r = \frac{\omega b}{V} \cdot \frac{V T_r}{b} = \frac{K}{K_r}$$

Thus there is a characteristic quantity K_r which includes both T_r and its associated velocity in such a fashion that K_r is a function only of reduced frequency K since equation (5) becomes

$$K_r = K \left\{ - \frac{2(\frac{1}{2} + a)F - 2(\frac{1}{4} - a^2)KG + (\frac{1}{8} + a^2)K^2}{2(\frac{1}{2} + a)G + 2(\frac{1}{4} - a^2)KF - (\frac{1}{2} - a)K} \right\} \quad (7)$$

The basic equation (1) becomes,

$$\frac{dC_m}{d(\omega t)} = \frac{dC_m}{2\pi d(\frac{t}{T})} = \frac{-1}{\frac{K}{K_r}} \Delta C_m, \quad \text{where } T = \frac{2\pi}{\omega} \quad (8)$$

which shows that the rate of change of C_m based on a time scale related to the motion is proportional to ΔC_m where the factor of proportionality depends only on the reduced frequency K . Equation (4) becomes,

$$C_m = C_{m_i} + \frac{1 - i(\frac{K}{K_r})}{1 + (\frac{K}{K_r})^2} \lambda \alpha_o e^{i\omega t} \quad (9)$$

which corresponds to an elliptical contour on the moment vs. angle of attack plane. The center of the ellipse is at (C_{m_i}, α_i) ; the line joining the center with $C_{m_{\max}}$ and $C_{m_{\min}}$ is of slope λ ; and both the eccentricity of the ellipse and the slope λ depend only on the reduced frequency K .

Proceeding now to oscillations which are partly or altogether in the stall region certain observations can be made from the experimental results which can be a guide in extending the analytical technique.

The variation of the moment with angle of attack apparently can assume quite a variety of shapes as shown in Figure 16 and in Plates 26 through 35 but certain general characteristics can be observed. For oscillation into and out of the stall region,

1. The unstalled portion of the moment variation is essentially a part of the ellipse easily determined from the equations based on the dynamic slope λ .
2. In the stalled portion, the moment at any angle of attack appears to tend toward the steady-state value of moment at that angle in a manner very similar to that below the stall. Usually these stalled steady-state values can be approximated by a straight line with a decidedly negative slope.

MASSACHUSETTS INSTITUTE OF TECHNOLOGY
Department of Aeronautical Engineering

CONTRACT NO. NAW-5693

PAGE 49

3. The actual stall occurs at an angle of attack above the steady-state stall angle but usually below the peak angle of attack of the oscillation. (See Plates 36 through 41) The recovery begins approximately at the steady-state stall angle.

For oscillations which are entirely above the stall such as the curve on the right side of Figure 16, the moment variation is approximately elliptical and appears to be related to its steady-state slope in a manner similar to the relation below the stall.

Following these observations, it is possible to make some assumptions which enable an attempt at prediction of the moment variation.

1. For the unstalled portion of the cycle use the appropriate part of the ellipse given by equation (9).
2. Assume that the same basic equation

$$\frac{dC_m}{d(\omega t)} = - \frac{\Delta C_m}{K/K_r} \quad (8)$$

holds in the stalled portion of the cycle.

3. Assume that $K_r (= \frac{b}{V T_r})$ has the same value at all points of the cycle.
4. Replace the steady-state variation of moment versus angle of attack with a line of slope λ in the unstalled range and one or more straight lines in the stalled range.

The assumed constancy of K_r can be checked either by direct measurement of slope on the experimental records or from the value of work per cycle obtained by graphical integration. An accurate measure of the slope, while subject to large uncertainties, gives a direct measure of K_r at any point in the cycle, whereas the value obtained from work gives a sort of average for a cycle. Numerous measurements of both types have been made and the results plotted on Plate 68 against the theoretical variation computed for the correct value of a . The comparison reveals the encouraging indication that K_r for stalled flow is certainly the same order of magnitude as for unstalled flow. It should be remembered however that these measurements all come from data obtained at one velocity so that the results are somewhat limited in scope.

A number of moment variations were computed using these basic assumptions by a computer who was familiar with the general shapes obtained experimentally but did not have prior access to the particular experimental plots corresponding to his predictions. In some cases it was assumed that the angle at which stall occurred was the peak angle reached;

PAGE 51

in others, stall angles were interpolated from the experimental curves of Plates 36 through 41. To make reasonable transitions at stall and recovery from stall from the ellipse associated with one straight line section of the moment curve to the ellipse associated with the other step by step integration was used. The results are plotted on Plates 69 through 73 and can be compared with the corresponding experimental curves included in Plates 26 through 35. A tabular summary of the results appears on Figure 17.

The predictions are reasonable approximations of the actual variations especially in some very important respects. The work per cycle and overall amplitude are in good agreement with the experimental values for all the cases tried which included a considerable variation in frequency and airfoil shape. The phase angle however, is in poor agreement unless a good estimate is made of the stalling angle.

Thus it appears that a reasonably reliable plot of work per cycle or damping coefficient j_s versus reduced frequency could be constructed for various initial angles of attack and amplitudes of oscillation provided the pertinent steady state moment data is available. At present, of course, the accuracy of such predictions is known to be reasonable only in the general Reynolds Number and reduced frequency ranges for which the above calculations were carried out.

As stated earlier in this section, it may also be desirable to be able to predict the variation in the stall range of lift caused by pitching. Although no such attempt has been made, a procedure similar to that used above may be possible.

If it is assumed, just as for moment, that,

$$\frac{dC_L}{dt} = - \frac{\Delta C_L}{T_L}$$

and,

$$\Delta C_L = C_L - (C_{L_i} + \lambda_L \alpha)$$

the expression for C_L at low initial angles of attack becomes

$$C_L = C_{L_i} + \frac{\lambda_L \alpha_0}{1 + (\omega T_L)^2} (1 - i\omega T_L) e^{i\omega t}$$

The classical expression for lift due to pitch is (Reference 15)

MASSACHUSETTS INSTITUTE OF TECHNOLOGY
Department of Aeronautical Engineering

PAGE 52

CONTRACT NO. NAW-6593

$$C_L = C_{L_i} + \frac{\pi}{2} \alpha_{oe} i \omega t \left\{ \left[-aK^2 - 2F + 2\left(\frac{1}{2} - a\right)KG \right] - i \left[K + 2G + 2\left(\frac{1}{2} - a\right)KF \right] \right\}$$

Comparison of the two expressions produces the relations,

$$\omega T_L = - \frac{K + 2G + 2\left(\frac{1}{2} - a\right)KF}{aK^2 + 2F - 2\left(\frac{1}{2} - a\right)KG}$$

$$\lambda_L = - \frac{\pi}{2} \left[aK^2 + 2F - 2\left(\frac{1}{2} - a\right)KG \right] \left[1 + (\omega T_L)^2 \right]$$

which are similar to Equations (5) and (6). Of course, the product ωT_L can be replaced by a reduced frequency ratio of the form K/K_L so that K_L and λ_L are functions only of the reduced frequency.

Thus lift due to pitch for low initial angles of attack can be described in a manner very similar to that used previously for moment. Whether a similar procedure can be used at and above the stall is not yet known.

PAGE 53

VI - CONCLUSIONS

The aerodynamic reactions on a wing oscillating sinusoidally at or near the stall vary in a periodic but definitely non-sinusoidal manner. The form of the periodic variations, which is usually evaluated in terms of its fundamental components, depends on the mean angle of attack, the frequency parameter, the airfoil shape, the amplitude of oscillation, the Reynolds number, and, in the case of a pitching motion, on the location of the rotational axis. This large number of important variables increases the difficulty of predicting, or even measuring, the aerodynamic reactions far beyond the known complexity of the classical case at zero mean angle of attack.

Most of the measurements to date have been confined to observations of the aerodynamic moment resulting from a sinusoidal pitching oscillation, although the M.I.T. data presented in this report are a valuable source of information on the behavior of lift as well as moment in both pitching and translational oscillations. Representative results from the various sources of data have been reproduced in graphical form in this report but because of the large number of significant parameters involved only a few general conclusions can be drawn.

It appears that the variation of torsional damping with mean angle of attack, which can be rather precipitous in the general reduced frequency range of 0.1 to 0.6 for Reynolds numbers of the order of 10^6 and less, becomes quite small for comparatively large values of reduced frequency and Reynolds number. This is particularly significant in the light of the demonstrated importance in stall flutter of variations in torsional damping. Airfoil shape affects primarily the suddenness and type of flow breakaway under dynamic stalling conditions and, of course, together with Reynolds number determines the range of angles of attack in which stalling will occur. This last observation illustrates the inadequacy for this type of work of referring angle of attack to the zero lift condition. A more useful and meaningful reference is the angle of stall on the steady-state lift curve at the test Reynolds number for the airfoil in question. The effects on torsional damping of amplitude of oscillation and of rotational axis position, while fairly pronounced in some instances are for the most part quite thoroughly obscured and distorted by the variations of the other parameters.

No instances of negative damping have been observed in the case of pure translation although it appears that negative damping may possibly occur for values of the reduced frequency of about 0.05 or less. Inasmuch as stall flutter is ordinarily predominantly a torsional motion and the aerodynamic reactions associated with the rotational component are of a much greater magnitude than those associated with the

MASSACHUSETTS INSTITUTE OF TECHNOLOGY
Department of Aeronautical Engineering

PAGE 54

CONTRACT NO.

translational part of the motion, it is likely that further measurements for pure translation will produce no useful results.

No serious attempt has apparently been made to predict the aerodynamic reactions under dynamic stalling conditions except for moment in pure pitch as has been proposed by Haley earlier in this report. This rather promising technique which requires only the appropriate steady-state lift and moment curves includes to some extent in its prediction the effect of all of the important parameters in what appear to be their critical ranges. Extension of this technique to the prediction of lift in pitch appears possible.

Considerable data on time average values of lift and moment are available for the first time in this report and should prove useful in estimation of average or mean deflections of an airfoil such as a propeller blade for which a stall flutter prediction is being attempted.

The observation and prediction of stall flutter itself has led to several interesting conclusions. As mentioned above most cases of stall flutter have exhibited a predominantly torsional motion with critical speeds much lower than predicted or observed at zero mean angle of attack. This difference in critical speeds usually reaches a maximum for mean angle not far from the steady-state stall angle and becomes less and less pronounced as the reduced frequency becomes large. Stall flutter should be differentiated from the forced excitation near a natural frequency which is often associated with the shedding of the well-known Kármán vortex trail. Stall flutter involves the interaction of airfoil motion and aerodynamic reactions whereas the Kármán vortices are observed behind even stationary objects.

The prediction of stall flutter has been approached by attempting to modify adequately the usual classical theory and has been moderately successful in a limited range. All of the results so far obtained indicate the major importance of changes in torsional damping and when adequate experimental information on this parameter was introduced into the calculations the predicted stall flutter speeds approximated the experimental values quite closely. However it also seems evident that even though stall flutter is predominantly torsional in character it can not be reduced to a single degree of freedom problem. The motion appears to be torsional only because rotation and translation of the reference axis are either almost exactly in phase or exactly out of phase. In the several cases examined closely the critical condition involved a balance between the damping in the translational motion and the pitching motion, both referred to the elastic axis. The lift arising from the pitching motion collaborates with what seems like quite a small amplitude translational motion to produce a large amount of negative damping. Thus although the stall flutter motion appears to be quite elementary, that appearance merely hides the basic complexity of the energy balance.
